Abstract

Using a 2-loop approximation for β -functions, we have considered the corresponding renormalization group improved effective potential in the Dual Abelian Higgs Model (DAHM) of scalar monopoles and calculated the phase transition (critical) couplings in U(1) and SU(N) regularized gauge theories. In contrast to our previous result $\alpha_{crit} \approx 0.17$, obtained in the one-loop approximation with the DAHM effective potential (see Ref.[20]), the critical value of the electric fine structure constant in the 2-loop approximation, calculated in the present paper, is equal to $\alpha_{crit} \approx 0.208$ and coincides with the lattice result for compact QED [10]: $\alpha_{crit}^{lat} \approx 0.20 \pm 0.015$. Following the 't Hooft's idea of the "abelization" of monopole vacuum in the Yang-Mills theories, we have obtained an estimation of the SU(N) triple point coupling constants, which is $\alpha_{N,crit}^{-1} = \frac{N}{2} \sqrt{\frac{N+1}{N-1}} \alpha_{U(1),crit}^{-1}$. This relation was used for the description of the Planck scale values of the inverse running constants $\alpha_i^{-1}(\mu)$ (i=1,2,3 correspond to U(1), SU(2) and SU(3) groups), according to the ideas of the Multiple Point Model [16].

1 Introduction

Lattice gauge theories, first introduced by K.Wilson [1] for studying the problem of confinement, are described by the following simplest action:

$$S = -\frac{\beta}{N} \sum_p \text{Re}(\text{Tr} \mathcal{U}_p), \quad (1)$$

where the sum runs over all plaquettes of a hypercubic lattice and $\mathcal{U}_p$ is the product around the plaquette p of the link variables in the N -dimensional fundamental representation of the gauge group G . Monte Carlo simulations of these simple Wilson lattice theories in 4 dimensions showed a (or an almost) second-order deconfining phase transition for $U(1)$ [2],[3], a crossover behavior for $SU(2)$ and $SU(3)$ [4],[5], and a first-order phase transition for $SU(N)$ with $N \geq 4$ [6]. Bhanot and Creutz [7],[8] have generalized the simple Wilson action, introducing two parameters in action:

$$S = \sum_p \left[-\frac{\beta_f}{N} \text{Re}(\text{Tr} \mathcal{U}_p) - \frac{\beta_A}{N^2 - 1} \text{Re}(\text{Tr}_A \mathcal{U}_p) \right], \quad (2)$$

where Tr_A is the trace in the adjoint representation of $SU(N)$. The phase diagrams, obtained for the generalized lattice $SU(2)$ and $SU(3)$ theories (2) by Monte Carlo methods in Refs.[7],[8], showed the existence of a triple point which is a boundary point of three first-order phase transitions: the "Coulomb-like" and $SU(N)/Z_N$ and Z_N confinement phases meet together at this point. From the triple point emanate three phase border lines which separate the corresponding phases. The Z_N phase transition is a "discreteness" transition, occurring when lattice plaquettes jump from the identity to nearby elements in the group. The $SU(N)/Z_N$ phase transition is due to a condensation of monopoles (a consequence of the non-trivial Π_1 of the group).

Monte Carlo simulations of the $U(1)$ gauge theory, described by the two-parameter lattice action [9],[10]:

$$S = \sum_p [\beta^{lat} \cos \Theta_p + \gamma^{lat} \cos 2\Theta_p], \quad \text{where} \quad \mathcal{U}_p = e^{i\Theta_p}, \quad (3)$$

also indicate the existence of a triple point on the corresponding phase diagram: "Coulomb-like", totally confining and Z_2 confining phases come together at this triple point.

The next efforts of the lattice simulations of the $SU(N)$ gauge theories may be found in the review [11].

The lattice artifact monopoles are responsible for the confinement mechanism in lattice gauge theories what is confirmed by many numerical and theoretical investigations (see reviews [12] and papers [13]). The simplest effective dynamics describing the confinement mechanism in the pure gauge lattice $U(1)$ theory is the Dual Abelian Higgs Model (DAHM) of scalar monopoles [14].

As it was shown in a number of investigations (see [12],[13] and references there), the confinement in the $SU(N)$ lattice gauge theories effectively comes to the same $U(1)$

formalism. The reason is the Abelian dominance in their monopole vacuum: monopoles of the Yang–Mills theory are the solutions of the $U(1)$ –subgroups, arbitrary embedded into the $SU(N)$ group. After a partial gauge fixing (Abelian projection by 't Hooft [15]) $SU(N)$ gauge theory is reduced to an Abelian $U(1)^{N-1}$ theory with $N-1$ different types of Abelian monopoles. Choosing the Abelian gauge for dual gluons, it is possible to describe the confinement in the lattice $SU(N)$ gauge theories by the analogous dual Abelian Higgs model of scalar monopoles.

In our previous papers [16]–[18] the calculations of the $U(1)$ phase transition (critical) coupling constant were connected with the existence of artifact monopoles in the lattice gauge theory and also in the Wilson loop action model [18]. But in Refs.[19],[20] we have considered the Higgs monopole model approximating the lattice artifact monopoles as fundamental pointlike particles described by Higgs scalar field. Using a one–loop renormalization group improvement of the effective Coleman–Weinberg potential [21] written for the dual sector of scalar electrodynamics, we have calculated in [20] the $U(1)$ critical values of the magnetic fine structure constant $\tilde{\alpha}_{crit} = g_{crit}^2/4\pi \approx 1.48$ and electric fine structure constant $\alpha_{crit} = \pi/g_{crit}^2 \approx 0.17$ (by the Dirac relation). These values are very close to the lattice result [10] for the compact QED described by the simple Wilson action corresponding to the case $\gamma^{lat} = 0$ in Eq.(3):

$$\alpha_{crit}^{lat} \approx 0.20 \pm 0.015 \quad \text{and} \quad \tilde{\alpha}_{crit}^{lat} \approx 1.25 \pm 0.10. \quad (4)$$

In the present paper we have considered a two–loop approximation for the renormalization group improved effective potential in the same DAHM of scalar monopoles (Section 2). We have obtained the following result: $\alpha_{crit} \approx 0.208$, which coincides with the lattice result (4).

Using the idea of the "abelization" of the monopole vacuum in the $SU(N)$ lattice gauge theories, we have developed a method of theoretical estimation of the $SU(N)$ critical couplings (see Section 3).

Investigating the phase transition in the dual Higgs monopole model, we have pursued two objects. From one side, we had an aim to explain the lattice results. But we had also another aim.

According to the Multiple Point Model (MPM) [16], there is a multiple critical point at the Planck scale where vacua of all fields existing in Nature are degenerate. Having at the Planck scale the phase transitions in $U(1)$, $SU(2)$ and $SU(3)$ sectors of the fundamental regularized gauge theory, it is natural to assume that the objects responsible for these transitions are the physically existing Higgs scalar monopoles which have to be introduced into theory as fundamental fields. Our present calculations indicate that the corresponding critical couplings coincide with the lattice ones, confirming the idea of Ref.[16]. Sections 4 and 6 are devoted to this problem.

2 Higgs monopole model renormalization group equations with two-loop approximation for beta-functions

As it was mentioned in Introduction, the DAHM of scalar monopoles describes the dynamics of confinement in lattice theories. This model, first suggested in Refs.[14], considers the following Lagrangian:

$$L = -\frac{1}{4g^2}F_{\mu\nu}^2(B) + \frac{1}{2}|\partial_\mu - iB_\mu\Phi|^2 - U(\Phi), \quad (5)$$

where

$$U(\Phi) = \frac{1}{2}\mu^2|\Phi|^2 + \frac{\lambda}{4}|\Phi|^4 \quad (6)$$

is the Higgs potential of scalar monopoles with magnetic charge g , and B_μ is the dual gauge field interacting with the monopole field Φ . In this model μ^2 is negative.

In Eqs.(5),(6) the complex scalar field Φ contains the Higgs (ϕ) and Goldstone (χ) boson fields:

$$\Phi = \phi + i\chi. \quad (7)$$

The effective potential in the Higgs model of scalar electrodynamics was first calculated by Coleman and Weinberg [21] in the one-loop approximation. The general methods of its calculation is given in review [22]. The effective potential $V_{eff}(\phi_c)$ is a function of the classical field ϕ_c [21]:

$$V_{eff}(\phi_c) = \sum_n \frac{-1}{n!} \Gamma^{(n)}(0) \phi_c^n, \quad (8)$$

where $\Gamma^{(n)}(0)$ is the one-particle irreducible n -point Green's function calculated at zero external momenta.

The RGE for the effective potential means that the potential cannot depend on a change in the arbitrary parameter – renormalization scale M , i.e. $dV_{eff}/dM = 0$. The effects of changing it are absorbed into changes in the coupling constants, masses and fields, giving so-called running quantities.

Considering the RG improvement of the effective potential [21], [22] and choosing the evolution variable as

$$t = \log(\phi^2/M^2), \quad (9)$$

we have the following RGE for the improved $V_{eff}(\phi^2)$ with $\phi^2 \equiv \phi_c^2$ [23]:

$$(M^2 \frac{\partial}{\partial M^2} + \beta_\lambda \frac{\partial}{\partial \lambda} + \beta_g \frac{\partial}{\partial g^2} + \beta_{(\mu^2)} \mu^2 \frac{\partial}{\partial \mu^2} - \gamma \phi^2 \frac{\partial}{\partial \phi^2}) V_{eff}(\phi^2) = 0, \quad (10)$$

where γ is the anomalous dimension and $\beta_{(\mu^2)}$, β_λ and β_g are the RG β -functions for mass, scalar and gauge couplings, respectively. RGE (10) leads to the following form of the improved effective potential [21]:

$$V_{eff} = \frac{1}{2} \mu_{run}^2(t) G^2(t) \phi^2 + \frac{1}{4} \lambda_{run}(t) G^4(t) \phi^4, \quad (11)$$

where μ_{run}^2 and λ_{run} are the running squared mass of scalar monopoles and their self-interaction constant, respectively, and (in our notations):

$$G(t) = \exp\left[-\frac{1}{2} \int_0^t dt' \gamma(g_{run}(t'), \lambda_{run}(t'))\right]. \quad (12)$$

A set of ordinary differential equations (RGE) corresponds to Eq.(10):

$$\frac{d\lambda_{run}}{dt} = \beta_\lambda(g_{run}(t), \lambda_{run}(t)), \quad (13)$$

$$\frac{d\mu_{run}^2}{dt} = \mu_{run}^2(t) \beta_{(\mu^2)}(g_{run}(t), \lambda_{run}(t)), \quad (14)$$

$$\frac{dg_{run}^2}{dt} = \beta_g(g_{run}(t), \lambda_{run}(t)). \quad (15)$$

So far as the mathematical structure of the DAHM is equivalent to the Higgs scalar electrodynamics, we can use all results of the last theory in our calculations, replacing the electric charge e and photon field A_μ by magnetic charge g and dual gauge field B_μ .

The RG β -functions for different renormalizable gauge theories with semisimple group have been calculated in the two-loop approximation [24]-[29] and even beyond [30]. But in this paper we made use the results of Refs.[24] and [27] for calculation of β -functions and anomalous dimension in the two-loop approximation, applied to the DAHM with scalar fields (7). The higher approximations essentially depend on the renormalization scheme [30]. Thus, on the level of two-loop approximation we have:

$$\beta_\lambda = \beta_\lambda^{(1)} + \beta_\lambda^{(2)}, \quad (16)$$

where

$$\beta_\lambda^{(1)} = \frac{1}{16\pi^2}(10\lambda^2 - 6g^2\lambda + 3g^4) \quad (17)$$

and

$$\beta_\lambda^{(2)} = \frac{1}{(16\pi^2)^2}(-25\lambda^3 + \frac{15}{2}g^2\lambda^2 - \frac{229}{12}g^4\lambda - \frac{59}{6}g^6). \quad (18)$$

The corresponding β -function for the squared running mass is:

$$\beta_{(\mu^2)} = \beta_{(\mu^2)}^{(1)} + \beta_{(\mu^2)}^{(2)}, \quad (19)$$

where

$$\beta_{(\mu^2)}^{(1)} = -\frac{3g^2}{16\pi^2} + \frac{\lambda}{4\pi^2} \quad (20)$$

and

$$\beta_{(\mu^2)}^{(2)} = \frac{1}{(16\pi^2)^2}(\frac{31}{12}g^4 + 3\lambda^2). \quad (21)$$

The gauge coupling β -function is given by Ref.[24]:

$$\beta_g = \beta_g^{(1)} + \beta_g^{(2)} = \frac{g^4}{48\pi^2} + \frac{g^6}{(16\pi^2)^2}. \quad (22)$$

Anomalous dimension follows from calculations made in Ref.[27]:

$$\gamma = \gamma^{(1)} + \gamma^{(2)} = -\frac{3g^2}{16\pi^2} + \frac{1}{(16\pi^2)^2} \frac{31}{12} g^4. \quad (23)$$

In Eqs.(16-23) and below, for simplicity, we have used the following notations: $\lambda \equiv \lambda_{run}$, $g \equiv g_{run}$ and $\mu \equiv \mu_{run}$.

3 Calculation of the U(1) critical couplings in the Higgs monopole model using renormalization group equations

The effective potential (11) can have several minima. Their positions depend on g^2 , μ^2 and λ . If the first local minimum occurs at $\phi = 0$ and $V_{eff}(0) = 0$, it corresponds to the Coulomb-like phase. In the case when the effective potential has the second local minimum at $\phi = \phi_{min} \neq 0$ with $V_{eff}^{min}(\phi_{min}^2) < 0$, we have the confinement phase. The phase transition between the "Coulomb-like" and confinement phases is given by the condition when the first local minimum at $\phi = 0$ is degenerate with the second minimum at $\phi = \phi_0$. These degenerate minima are shown in Fig.1 by the curve 1. They correspond to the different vacua arising in this model. And the dashed curve 2 describes the appearance of two minima corresponding to the confinement phases (see details in Ref.[20]).

The conditions of the existence of degenerate vacua are given by the following equations:

$$V_{eff}(0) = V_{eff}(\phi_0^2) = 0, \quad (24)$$

$$\frac{\partial V_{eff}}{\partial \phi}|_{\phi=0} = \frac{\partial V_{eff}}{\partial \phi}|_{\phi=\phi_0} = 0, \quad (25)$$

and inequalities

$$\frac{\partial^2 V_{eff}}{\partial \phi^2}|_{\phi=0} > 0, \quad \frac{\partial^2 V_{eff}}{\partial \phi^2}|_{\phi=\phi_0} > 0. \quad (26)$$

The first equation (24) applied to Eq.(11) gives:

$$\mu_{run}^2 = -\frac{1}{2} \lambda_{run}(t_0) \phi_0^2 G^2(t_0), \quad (27)$$

where $t_0 = \log(\phi_0^2/M^2)$.

Using a notation:

$$V'_{eff}(\phi_0^2) \equiv \frac{\partial V_{eff}}{\partial \phi^2}|_{\phi=\phi_0}, \quad (28)$$

we have the condition:

$$V'_{eff}(\phi_0^2) = 0, \quad (29)$$

according to the second equation in (25). Calculating the first derivative of V_{eff} , we obtain the following expression:

$$V'_{eff}(\phi^2) = \frac{V_{eff}(\phi^2)}{\phi^2} \left(1 + 2 \frac{d \log G}{dt}\right) + \frac{1}{2} \frac{d \mu_{run}^2}{dt} G^2(t)$$

$$+ \frac{1}{4} \left(\lambda_{run}(t) + \frac{d\lambda_{run}}{dt} + 2\lambda_{run} \frac{d \log G}{dt} \right) G^4(t) \phi^2. \quad (30)$$

From Eq.(12), we have:

$$\frac{d \log G}{dt} = -\frac{1}{2} \gamma. \quad (31)$$

It is easy to find the joint solution of equations

$$V_{eff}(\phi_0^2) = V'_{eff}(\phi_0^2) = 0. \quad (32)$$

Using RGE (13), (14) and Eqs.(27), (31), we obtain:

$$V'_{eff}(\phi_0^2) = \frac{1}{4} (-\lambda_{run} \beta_{(\mu^2)} + \lambda_{run} + \beta_\lambda - \gamma \lambda_{run}) G^4(t_0) \phi_0^2 = 0, \quad (33)$$

or

$$\beta_\lambda + \lambda_{run}(1 - \gamma - \beta_{(\mu^2)}) = 0. \quad (34)$$

Substituting β_λ , $\beta_{(\mu^2)}$ and γ , given by Eqs.(16–21) and (23), we obtain from Eq.(34) the following equation:

$$3y^2 - 16\pi^2 + 6x^2 + \frac{1}{16\pi^2} (28x^3 + \frac{15}{2}x^2y + \frac{97}{4}xy^2 - \frac{59}{6}y^3) = 0, \quad (35)$$

where $x = -\lambda_{PT}$ and $y = g_{PT}^2$ are the phase transition values of $-\lambda_{run}$ and g_{run}^2 . The curve (35) describes a border between the "Coulomb-like" ($V_{eff} \geq 0$) and confinement ($V_{eff}^{min} < 0$) phases. Choosing a physical branch corresponding to $g^2 \geq 0$ and $g^2 \rightarrow 0$, when $\lambda \rightarrow 0$, we have received curve 2 on the phase diagram ($\lambda_{run}; g_{run}^2$) shown in Fig.2. This curve corresponds to the 2-loop approximation and can be compared with the curve 1 of Fig.2, which describes the same phase border calculated in Ref.[20] in the 1-loop approximation. In the previous paper [20] we have emphasized that our accuracy of the 1-loop approximation is not excellent and can commit errors of order 30%. Curves 1,2 resemble this situation.

According to the phase diagram drawn in Fig.2, the confinement phase begins at $g^2 = g_{max}^2$ (see details in Ref.[20]) and exists at $g^2 \leq g_{max}^2$. Therefore, we have:

$$g_{crit}^2 = g_{max1}^2 \approx 18.61 \quad - \quad \text{in the 1-loop approximation,}$$

and

$$g_{crit}^2 = g_{max2}^2 \approx 15.11 \quad - \quad \text{in the 2-loop approximation.} \quad (36)$$

We see the deviation of results of order 20%.

In the 2-loop approximation:

$$\tilde{\alpha}_{crit} = \frac{g_{crit}^2}{4\pi} \approx 1.20, \quad (37)$$

instead of the result $\tilde{\alpha}_{crit} \approx 1.48$ obtained in the 1-loop approximation.

Using the Dirac relation for elementary charges:

$$eg = 2\pi, \quad \text{or} \quad \alpha \tilde{\alpha} = \frac{1}{4}, \quad (38)$$

we get a 2-loop approximation result for the critical electric fine structure constant:

$$\alpha_{crit} = \frac{1}{4\tilde{\alpha}_{crit}} \approx 0.208. \quad (39)$$

This result coincides with the lattice result (4) obtained for the compact QED by Monte Carlo methods [10]. Eqs.(4) and (39) give the following result for the inverse electric fine structure constant:

$$\alpha_{crit}^{-1} \approx 5. \quad (40)$$

This value is important for the phase transition at the Planck scale (see Sections 4 and 6). Now we are able to estimate the validity of 2-loop approximation for all β -functions and γ , calculating the corresponding ratios of 2-loop contributions to 1-loop contributions at the maxima of curves 1 and 2:

$\lambda_{crit} = \lambda_{run}^{max1} \approx -13.16$ $g_{crit}^2 = g_{max1}^2 \approx 18.61$ $\frac{\gamma^{(2)}}{\gamma^{(1)}} \approx -0.0080$ $\frac{\beta_{\mu^2}^{(2)}}{\beta_{\mu^2}^{(1)}} \approx -0.0826$ $\frac{\beta_{\lambda}^{(2)}}{\beta_{\lambda}^{(1)}} \approx 0.1564$ $\frac{\beta_g^{(2)}}{\beta_g^{(1)}} \approx 0.3536$	$\lambda_{crit} = \lambda_{run}^{max2} \approx -7.13$ $g_{crit}^2 = g_{max2}^2 \approx 15.11$ $\frac{\gamma^{(2)}}{\gamma^{(1)}} \approx -0.0065$ $\frac{\beta_{\mu^2}^{(2)}}{\beta_{\mu^2}^{(1)}} \approx -0.0637$ $\frac{\beta_{\lambda}^{(2)}}{\beta_{\lambda}^{(1)}} \approx 0.0412$ $\frac{\beta_g^{(2)}}{\beta_g^{(1)}} \approx 0.2871$	(41)
---	--	--------

Here we see that all ratios are sufficiently small, i.e. all 2-loop contributions are small in comparison with 1-loop contributions, confirming the validity of perturbation theory in the 2-loop approximation, considered in this model. The accuracy of deviation is worse ($\sim 30\%$) for β_g -function. But it is necessary to emphasize that calculating the border curves 1 and 2 we have not used RGE (22) for monopole charge: β_g -function is absent in Eq.(34). This means that we can expect a nice accuracy for g_{crit}^2 calculated with help of Eq.(35).

The above-mentioned β_g -function appears only in the second order derivative of V_{eff} which is related with monopole mass m :

$$V_{eff}''(\phi_0^2) = \frac{1}{2\phi_0^2} \frac{\partial^2 V_{eff}}{\partial \phi^2} \Big|_{\phi=\phi_0} = \frac{m^2}{2\phi_0^2}. \quad (42)$$

As it was shown in Ref.[20], $V_{eff}'' \rightarrow 0$ and monopole acquires a zero mass near the critical point $(\lambda_{crit}; g_{crit}^2)$. This result is in agreement with the result of compact QED described by the Villain action [31]: $m^2 \approx 0$ in the vicinity of the critical point.

4 Multiple Point Model and critical values of the U(1) and SU(N) fine structure constants

A lot of investigations were devoted to the question: "What comes beyond the Standard Model?". Grand Unification Theories (GUTs), unifying all gauge interactions, were constructed and the role of supersymmetry in GUTs was investigated as very promising. Unfortunately, at present time experiment does not indicate any manifestation of the supersymmetry. In this connection, the Anti-Grand Unification Theory (AGUT) was developed in Refs.[32]-[37] as a realistic alternative to SUSY GUTs. According to this theory, supersymmetry does not come into the existence up to the Planck energy scale:

$$\mu_{Pl} = 1.22 \cdot 10^{19} \text{ GeV}. \quad (43)$$

The Standard Model (SM) is based on the group:

$$SMG = SU(3)_c \otimes SU(2)_L \otimes U(1)_Y. \quad (44)$$

The AGUT suggests that at the scale $\mu_G \sim \mu_{Pl}$ there exists the more fundamental group G containing N_{gen} copies of the Standard Model Group SMG:

$$G = SMG_1 \otimes SMG_2 \otimes \dots \otimes SMG_{N_{gen}} \equiv (SMG)^{N_{gen}}, \quad (45)$$

where N_{gen} designates the number of quark and lepton generations.

If $N_{gen} = 3$ (as AGUT predicts), then the fundamental gauge group G is:

$$G = (SMG)^3 = SMG_1 \otimes SMG_2 \otimes SMG_3, \quad (46)$$

or the generalized one:

$$G_f = (SMG)^3 \otimes U(1)_f, \quad (47)$$

which was suggested by the fitting of fermion masses of the SM (see Refs.[34]).

Recently a new generalization of the AGUT was suggested in Refs.[36]:

$$G_{ext} = (SMG \otimes U(1)_{B-L})^3, \quad (48)$$

which takes into account the see-saw mechanism with right-handed neutrinos, also gives the reasonable fitting of the SM fermion masses and describes all neutrino experiments known today.

The AGUT approach is used in conjunction with the Multiple Point Principle (MPP) proposed in Ref.[16]. According to MPP, there is a special point — the Multiple Critical Point (MCP) — on the phase diagram of the fundamental regularized gauge theory G (or G_f , or G_{ext}), which is a point where the vacua of all fields existing in Nature are degenerate, having the same vacuum energy density. Such a phase diagram has axes given by all coupling constants considered in theory. Then all (or just many) numbers of phases meet at the MCP.

Multiple Point Model assumes the existence of MCP at the Planck scale, insofar as gravity may be "critical" at the Planck scale (in the sense of degenerate vacua).

The usual definition of the SM coupling constants:

$$\alpha_1 = \frac{5}{3} \frac{\alpha}{\cos^2 \Theta_{\overline{MS}}}, \quad \alpha_2 = \frac{\alpha}{\sin^2 \Theta_{\overline{MS}}}, \quad \alpha_3 \equiv \alpha_s = \frac{g_s^2}{4\pi}, \quad (49)$$

where α and α_s are the electromagnetic and SU(3) fine structure constants, respectively, is given in the Modified minimal subtraction scheme ($\overline{MS}$). Using RGE with experimentally established parameters, it is possible to extrapolate the experimental values of three inverse running constants $\alpha_i^{-1}(\mu)$ (here μ is an energy scale and $i=1,2,3$ correspond to U(1), SU(2) and SU(3) groups of the SM) from Electroweak scale to the Planck scale. The precision of the LEP data allows to make this extrapolation with small errors (see [38]). Assuming that these RGEs for $\alpha_i^{-1}(\mu)$ are contingent not encountering new particles up to $\mu \approx \mu_{Pl}$ and doing the extrapolation with one Higgs doublet under the assumption of a "desert", the following results for the inverses $\alpha_{Y,2,3}^{-1}$ (here $\alpha_Y \equiv \frac{3}{5}\alpha_1$) were obtained in Ref.[16] (compare with [38]):

$$\alpha_Y^{-1}(\mu_{Pl}) \approx 55.5; \quad \alpha_2^{-1}(\mu_{Pl}) \approx 49.5; \quad \alpha_3^{-1}(\mu_{Pl}) \approx 54.0. \quad (50)$$

The extrapolation of $\alpha_{Y,2,3}^{-1}(\mu)$ up to the point $\mu = \mu_{Pl}$ is shown in Fig.3.

According to the AGUT, at some point $\mu = \mu_G < \mu_{Pl}$ (but near μ_{Pl}) the fundamental group G (or G_f , or G_{ext}) undergoes spontaneous breakdown to the diagonal subgroup:

$$G \longrightarrow G_{\text{diag.subgr.}} = \{g, g, g | g \in SMG\}, \quad (51)$$

which is identified with the usual (lowenergy) group SMG. The point $\mu_G \sim 10^{18}$ GeV also is shown in Fig.3, together with a region of G-theory where AGUT works.

The AGUT prediction of the values of $\alpha_i(\mu)$ at $\mu = \mu_{Pl}$ is based on the MPP, which gives these values in terms of the critical couplings $\alpha_{i,crit}$ [32]-[37]:

$$\alpha_i(\mu_{Pl}) = \frac{\alpha_{i,crit}}{N_{gen}} = \frac{\alpha_{i,crit}}{3} \quad (52)$$

for $i=2,3$ and

$$\alpha_1(\mu_{Pl}) = \frac{\alpha_{1,crit}}{\frac{1}{2}N_{gen}(N_{gen} + 1)} = \frac{\alpha_{1,crit}}{6} \quad (53)$$

for U(1).

In Eqs.(52) and (53) $\alpha_{i,crit}$ are the triple point values of the effective fine structure constants given by the generalized lattice SU(3)-, SU(2)- and U(1)- gauge theories described by Eqs.(2) and (3).

The authors of Refs.[7]-[10] were not able to obtain the lattice triple point values of $\alpha_{i,crit}$ by the Monte Carlo simulation methods. These values were calculated theoretically in Ref.[16]. Using the lattice [7]-[10] triple point values of $(\beta_A; \beta_f)$ and $(\beta^{lat}; \gamma^{lat})$, the authors of Ref.[16] have obtained $\alpha_{i,crit}$ by so-called "Parisi improvement method" (see details in [16]):

$$\alpha_{Y,crit}^{-1} \approx 9.2 \pm 1, \quad \alpha_{2,crit}^{-1} \approx 16.5 \pm 1, \quad \alpha_{3,crit}^{-1} \approx 18.9 \pm 1. \quad (54)$$

According to MPM, assuming the existence of MCP at $\mu = \mu_{Pl}$, we have the following prediction of AGUT, substituting the results (54) in Eqs.(52) and (53):

$$\alpha_Y^{-1}(\mu_{Pl}) \approx 55 \pm 6; \quad \alpha_2^{-1}(\mu_{Pl}) \approx 49.5 \pm 3; \quad \alpha_3^{-1}(\mu_{Pl}) \approx 57.0 \pm 3. \quad (55)$$

These results coincide with the results (50) obtained by extrapolation of the experimental data to the Planck scale in the framework of the pure SM (without any new particles).

But now we see, that the first value of Eq.(54) gives $\alpha_{Y,crit}^{-1} \approx 9$ at the triple point of the generalized U(1) lattice theory, what is larger than the simple lattice result theory and Higgs monopole model result (39), obtained in this paper.

The next step of our paper is to explain the relation between the values of U(1) and SU(N) critical coupling constants (54).

5 Monopoles strength group dependence

Lattice gauge theories have lattice artifact monopoles. We suppose that only those lattice artifact monopoles are important for the phase transition calculations which have the smallest monopole charges. Let us consider the lattice gauge theory with the gauge group $SU(N)/Z_N$ as our main example. That is to say, we consider the adjoint representation action and do not distinguish link variables forming the same one multiplied by any element of the center of the group. The group $SU(N)/Z_N$ is not simply connected and has the first homotopic group $\Pi_1(SU(N)/Z_N)$ equal to Z_N . The lattice artifact monopole with the smallest magnetic charge may be described as a three-cube (or rather a chain of three-cubes, describing the time track) from which radiates magnetic field corresponding to $U(1)$ subgroup of gauge group $SU(N)/Z_N$ with the shortest length insight of this group but still homotopically non-trivial. In fact, this $U(1)$ subgroup is obtained by the exponentiating generator:

$$\frac{“\lambda_8”}{2} = \frac{1}{\sqrt{2N(N-1)}} \begin{pmatrix} N-1 & 0 & \dots & 0 \\ 0 & -1 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & -1 \end{pmatrix} \quad (56)$$

This specific form is one gauge choice; any similarity transformation of this generator would describe physically the same monopole. If one has somehow already chosen the gauge monopoles with different but similarity transformation related generators, they would be physically different. Thus, after gauge choice, there are monopoles corresponding to different directions of the Lie algebra generators in the form $\mathcal{U} \frac{“\lambda_8”}{2} \mathcal{U}^+$.

Now, when we want to apply the effective potential calculation as a technique for the getting phase diagram information for the condensation of the lattice artifact monopoles in the non-abelian lattice gauge theory, we have to correct the abelian case calculation for the fact that after gauge choice we have a lot of different monopoles. If a couple of monopoles happens to have their generators just in the same directions in the Lie algebra, they will interact with each other as Abelian monopoles (in first approximation).

In general, the interaction of two monopoles by exchange of a photon will be modified by the following factor:

$$\frac{\text{Tr}(\mathcal{U}_1 \frac{\lambda_8}{2} \mathcal{U}_1^\dagger \mathcal{U}_2 \frac{\lambda_8}{2} \mathcal{U}_2^\dagger)}{\text{Tr}(\frac{\lambda_8}{2})^2}. \quad (57)$$

We shall assume that we can correct these values of monopole orientations in the Lie algebra in a statistical way. That is to say, we want to determine an effective coupling constant $\tilde{g}_{eff}$ describing the monopole charge as if there is only one Lie algebra orientationwise type of monopole. It should be estimated statistically in terms of the monopolic charge $\tilde{g}_{genuine}$ valid to describe the interaction between monopoles with generators oriented along the same $U(1)$ subgroup. A very crude intuitive estimate of the relation between these two monopole charge concepts $\tilde{g}_{genuine}$ and $\tilde{g}_{eff}$ consists in playing that the generators are randomly oriented in the whole $N^2 - 1$ dimensional Lie algebra. When even the sign of the Lie algebra generator associated with the monopole is random — as we assumed in this crude argument — the interaction between two monopoles with just one photon exchanged averages out to zero. Therefore, we can get a non-zero result only in the case of exchange by two photons or more. That is, however, good enough for our effective potential calculation since only $\tilde{g}^4$ (but not the second power) occurs in the Coleman — Weinberg effective potential in the one-loop approximation (see [20]-[22]). Taking into account this fact that we can average imagining monopoles with generators along a basis vector in the Lie algebra, the chance of interaction by double photon exchange between two different monopoles is just $\frac{1}{N^2-1}$, because there are $N^2 - 1$ basis vectors in the basis of the Lie algebra. Thus, this crude approximation gives:

$$\tilde{g}_{eff}^4 = \frac{1}{N^2 - 1} \tilde{g}_{genuine}^4. \quad (58)$$

Note that considering the two photons exchange which is forced by our statistical description, we must concern the forth power of the monopole charge $\tilde{g}$.

The relation (58) was not derived correctly, but its validity can be confirmed if we use a more correct statistical argument. The problem with our crude estimate is that the generators making monopole charge to be minimal must go along the shortest type of $U(1)$ subgroups with non-trivial homotopy.

5.1 Correct averaging

The λ_8 -like generators $\mathcal{U} \frac{\lambda_8}{2} \mathcal{U}^\dagger$ maybe written as

$$\mathcal{U} \frac{\lambda_8}{2} \mathcal{U}^\dagger = -\sqrt{\frac{1}{2N(N-1)}} \mathbf{1} + \sqrt{\frac{N}{2(N-1)}} \mathcal{P} \quad (59)$$

where $\mathcal{P}$ is a projection metrics into one-dimensional state in the $\underline{N}$ representation. It is easy to see that averaging according to the Haar measure distribution of $\mathcal{U}$, we get the average of $\mathcal{P}$ projection on “quark” states with a distribution corresponding to the rotationally invariant one on the unit sphere in the N -dimensional $\underline{N}$ -Hilbert space.

If we denote the Hilbert vector describing the state on which $\mathcal{P}$ shall project as

$$\mathcal{P} = \begin{pmatrix} \psi_1 \\ \psi_2 \\ \vdots \\ \psi_N \end{pmatrix}, \quad (60)$$

then the probability distribution on the unit sphere becomes:

$$P\left(\begin{pmatrix} \psi_1 \\ \psi_2 \\ \vdots \\ \psi_N \end{pmatrix}\right) \prod_{i=1}^N d\psi_i \propto \delta(\sum_{i=1}^N |\psi_i|^2 - 1) \prod_{i=1}^N d(|\psi_i|^2). \quad (61)$$

Since, of course, we must have $|\psi_i|^2 \geq 0$ for all $i = 1, 2, \dots, N$, the δ -function is easily seen to select a flat distribution on a $(N - 1)$ -dimensional equilateral simplex. The average of the two photon exchange interaction given by the correction factor (57) squared (numerically):

$$\frac{\text{Tr}(\mathcal{U}_1 \frac{\lambda_8}{2} \mathcal{U}_1^+ \mathcal{U}_2 \frac{\lambda_8}{2} \mathcal{U}_2^+)^2}{\text{Tr}((\frac{\lambda_8}{2})^2)^2} \quad (62)$$

can obviously be replaced by the expression where we take as random only one of the “random“ λ_8 -like generators, while the other one is just taken as $\frac{\lambda_8}{2}$, i.e. we can take say $\mathcal{U}_2 = \mathbf{1}$ without changing the average.

Considering the two photon exchange diagram, we can write the correction factor (obtained by the averaging) for the fourth power of magnetic charge:

$$\frac{\tilde{g}_{eff}^4}{\tilde{g}_{genuine}^4} = \text{average}\left\{ \frac{\text{Tr}(\frac{\lambda_8}{2} \mathcal{U}_1 \frac{\lambda_8}{2} \mathcal{U}_1^+)^2}{\text{Tr}((\frac{\lambda_8}{2})^2)^2} \right\}. \quad (63)$$

Substituting the expression (59) in Eq.(63), we have:

$$\frac{\tilde{g}_{eff}^4}{\tilde{g}_{genuine}^4} = \text{average}\left\{ \frac{\text{Tr}(\frac{\lambda_8}{2} (-\sqrt{\frac{1}{2N(N-1)}} \mathbf{1} + \sqrt{\frac{N}{2(N-1)}} \mathcal{P}))^2}{\text{Tr}((\frac{\lambda_8}{2})^2)^2} \right\}. \quad (64)$$

Since $\frac{\lambda_8}{2}$ is traceless, we obtain using the projection (60):

$$\text{Tr}(\frac{\lambda_8}{2} \mathcal{P} \sqrt{\frac{N}{2(N-1)}}) = -\frac{1}{2(N-1)} + \frac{N}{2(N-1)} |\psi_1|^2. \quad (65)$$

The value of the square $|\psi_1|^2$ over the simplex is proportional to one of the heights in this simplex. It is obvious from the geometry of a simplex that the distribution of $|\psi_1|^2$ is

$$dP = (N-1)(1 - |\psi_1|^2)^{(N-2)} d(|\psi_1|^2), \quad (66)$$

where, of course, $0 \leq |\psi_1|^2 \leq 1$ only is allowed. In Eq.(66) P is a probability. By definition:

$$\text{average}\{f(|\psi_1|^2)\} = (N-1) \int_0^1 f(|\psi_1|^2) (1-|\psi_1|^2)^{(N-2)} d(|\psi_1|^2). \quad (67)$$

Then

$$\frac{\tilde{g}_{eff}^4}{\tilde{g}_{genuine}^4} = \frac{N^2}{(N-1)} \int_0^1 \left(\frac{1}{N} - |\psi_1|^2\right)^2 (1-|\psi_1|^2)^{N-2} d(|\psi_1|^2) \quad (68)$$

$$= \frac{N^2}{N-1} \int_0^1 \left(1-y-\frac{1}{N}\right)^2 y^{N-2} dy \quad (69)$$

$$= \frac{1}{N^2-1} \quad (70)$$

and we have confirmed our crude estimation (58).

5.2 Relative normalization of couplings

Now we are interested in how $\tilde{g}_{genuine}^2$ is related to $\alpha_N = g_N^2/4\pi$.

We would get the simple Dirac relation:

$$g_{(1)} \cdot \tilde{g}_{genuine} = 2\pi \quad (71)$$

if $g_{(1)} \equiv g_{U(1)\text{-subgroup}}$ is the coupling for the $U(1)$ -subgroup of $SU(N)$ normalized in such a way that the charge quantum $g_{(1)}$ corresponds to a covariant derivative $\partial_\mu - g_{(1)} A_\mu^{U(1)}$.

Now we shall follow the convention — usually used to define $\alpha_N = g_N^2/4\pi$ — that the covariant derivative for the $\underline{N}$ -plet representation is:

$$D_\mu = \partial_\mu - g_N \frac{\lambda^a}{2} A_\mu^a \quad (72)$$

with

$$Tr\left(\frac{\lambda^a}{2} \frac{\lambda^b}{2}\right) = \frac{1}{2} \delta^{ab}, \quad (73)$$

and the kinetic term for the gauge field is

$$L = -\frac{1}{4} F_{\mu\nu}^a F^{b\mu\nu}, \quad (74)$$

where

$$F_{\mu\nu}^a = \partial_\mu A_\nu^a - \partial_\nu A_\mu^a - g_N f^{abc} A_\mu^b A_\nu^c. \quad (75)$$

Especially if we want to choose a basis for our generalized Gell–Mann matrices so that one basic vector is our $\frac{\lambda_8}{2}$, then for $A_\mu^{\text{“8”}}$ we have the covariant derivation $\partial_\mu - g_N \frac{\lambda_8}{2} A_\mu^{\text{“8”}}$. If this covariant derivative is written in terms of the $U(1)$ -subgroup, corresponding to monopoles with the Dirac relation (71), then the covariant derivative has a form $\partial_\mu - g_{(1)} A_\mu^{\text{“8”}} \cdot \underline{M}$. Here $\underline{M}$ has the property that $\exp(i2\pi \underline{M})$ corresponds to the elements of the

group $SU(N)/Z_N$ going all around and back to the unit element. Of course, $\underline{M} = \frac{g_N}{g_{(1)}} \cdot \frac{“\lambda_8”}{2}$ and the ratio $g_N/g_{(1)}$ must be such one that $\exp(i2\pi \frac{g_N}{g_{(1)}} \frac{“\lambda_8”}{2})$ shall represent — after first return — the unit element of the group $SU(N)/Z_N$. Now this unit element really means the coset consisting of the center elements $\exp(i\frac{2\pi k}{N}) \in SU(N)$, ($k \in Z$), and the requirement of the normalization of $g_{(1)}$ ensuring the Dirac relation (71) is:

$$\exp(i2\pi \frac{g_N}{g_{(1)}} \frac{“\lambda_8”}{2}) = \exp(i\frac{2\pi}{N}) \mathbf{1}. \quad (76)$$

This requirement is satisfied if the eigenvalues of $\frac{g_N}{g_{(1)}} \frac{“\lambda_8”}{2}$ are modulo 1 equal to $-\frac{1}{N}$, i.e. formally we might write:

$$\frac{g_N}{g_{(1)}} \frac{“\lambda_8”}{2} = -\frac{1}{N} \pmod{1}. \quad (77)$$

According to (56), we have:

$$\frac{g_N}{g_{(1)}} \cdot \frac{1}{\sqrt{2N(N-1)}} \begin{pmatrix} N-1 & 0 & \cdots & 0 \\ 0 & -1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & -1 \end{pmatrix} = -\frac{1}{N} \pmod{1}, \quad (78)$$

what implies:

$$\frac{g_N}{g_{(1)}} = \sqrt{\frac{2(N-1)}{N}}, \quad (79)$$

or

$$\frac{g_N^2}{g_{(1)}^2} = \frac{2(N-1)}{N}. \quad (80)$$

6 The relation between U(1) and SU(N) critical couplings. The comparison with the Multiple Point Model results

Collecting the relations (80), (71) and (58), we get:

$$\begin{aligned} \alpha_N^{-1} &= \frac{4\pi}{g_N^2} = \frac{N}{2(N-1)} \cdot \frac{4\pi}{g_{(1)}^2} = \frac{N}{2(N-1)} \cdot \frac{\tilde{g}_{genuine}^2}{\pi} \\ &= \frac{N}{2(N-1)} \sqrt{N^2-1} \cdot \frac{\tilde{g}_{eff}^2}{\pi} = \frac{N}{2(N-1)} \sqrt{N^2-1} \cdot \frac{4\pi}{g_{U(1)}^2} = \frac{N}{2} \sqrt{\frac{N+1}{N-1}} \cdot \alpha_{U(1)}^{-1}, \end{aligned} \quad (81)$$

where

$$g_{U(1)} \tilde{g}_{eff} = 2\pi \quad (82)$$

and $\alpha_{U(1)} = g_{U(1)}^2/4\pi$.

The meaning of this relation is that provided that we have $\tilde{g}_{eff}$ the same for $SU(N)/Z_N$ and U(1) gauge theories the couplings are related according to Eq.(81).

We have a use for this relation when we want to calculate the phase transition couplings using the scalar monopole field responsible for the phase transition in the gauge groups $SU(N)/Z_N$. Having in mind the "Abelian" dominance in the $SU(N)$ monopole vacuum, we must think that $\tilde{g}_{eff}^{crit}$ coincides with g_{crit} of the $U(1)$ gauge theory. Of course, here we have an approximation taking into account only monopoles interaction and ignoring the relatively small selfinteractions of the Yang–Mills fields. In this approximation we obtain the same phase transition (triple point, or critical) $\tilde{g}_{eff}$ -coupling which is equal to g_{crit} of $U(1)$ whatever the gauge group $SU(N)$ might be. Thus we conclude that for the various groups $U(1)$ and $SU(N)/Z_N$, according to Eq.(81), we have the following relation between the phase transition couplings:

$$\alpha_{N,crit}^{-1} = \frac{N}{2} \sqrt{\frac{N+1}{N-1}} \alpha_{U(1),crit}^{-1}. \quad (83)$$

Using the relation (83), we obtain:

$$\alpha_{Y,crit}^{-1} : \alpha_{2,crit}^{-1} : \alpha_{3,crit}^{-1} = 1 : \sqrt{3} : 3/\sqrt{2} = 1 : 1.73 : 2.12. \quad (84)$$

Let us compare now these relations with the Multiple Point Model results (54). For $\alpha_{Y,crit}^{-1} \approx 9.2$ Eq.(84) gives:

$$\alpha_{Y,crit}^{-1} : \alpha_{2,crit}^{-1} : \alpha_{3,crit}^{-1} = 9.2 : 15.9 : 19.5. \quad (85)$$

Here we see that in the framework of errors the result (85) coincides with the AGUT–MPM prediction (54). It is necessary to take into account an approximate description of the confinement dynamics in the $SU(N)$ gauge theories which was used in this paper.

We are inclined to think that α_{crit} has approximately the same value along the whole (first order) phase transition border between the "Coulomb" and confinement phases on the corresponding lattice phase diagram (β^{lat} , γ^{lat}) (see Eq.(3) and Refs.[10]). We think that the discrepancy between α_{crit} given by Eq.(54) for $U(1)$ gauge theory and the corresponding result (40) obtained in the lattice investigations and in our Higgs monopole model, although they are of the same order, can be explained by different scales responsible for these phase transitions. In spite of this fact, it seems that the relation (83) is quite general, independent of the scale, although it is crude due to approximations considered in this paper.

7 Conclusions

In the present paper we have considered the Dual Abelian Higgs Model (DAHM) of scalar monopoles reproducing a confinement mechanism in lattice gauge theories. Using the Coleman–Weinberg idea of the RG improvement of the effective potential [21], we have considered the RG improved effective potential in the DAHM with β -functions calculated in the two-loop approximation. The phase transition between the Coulomb-like and confinement phases has been investigated in the $U(1)$ gauge theory by the method developed in Ref.[20]. As previously, critical coupling constants were calculated. Performing the comparison with results of the one-loop approximation obtained in Ref.[20], where

we have received $\alpha_{crit} \approx 0.17$ and $\tilde{\alpha}_{crit} \approx 1.48$, in this paper we see that the two-loop approximation gives the coincidence of the critical values of electric and magnetic fine structure constants ($\alpha_{crit} \approx 0.208$ and $\tilde{\alpha}_{crit} \approx 1.20$) with the lattice result (4). Also comparing the one-loop and two-loop contributions to beta-functions, we have demonstrated the validity of the perturbation theory in solution of the phase transition problem in the $U(1)$ gauge theory.

In the second part of our paper we have used the approximation of lattice artifact monopoles, being described by scalar "point" monopoles and represented by the Higgs scalar field, to reproduce the lattice phase transition couplings not only for the $U(1)$ case but also for the gauge groups $SU(N)/Z_N$ ($N=2,3$ especially). Since even the non-Abelian fields around the "lattice artifact" monopoles are taken as going in only one direction in the Lie algebra, the monopoles are really Abelian. The direction in the Lie algebra of their fields are, however, gauge independent and we used an averaging argumentation ending up with the relating the couplings corresponding to the biggest dual couplings and therefore essentially to the phase transition couplings by Eq.(81). This relation between the phase transition fine structure constants for the groups $U(1)$ and $SU(N)/Z_N$ is:

$$\alpha_{N,crit}^{-1} = \frac{N}{2} \sqrt{\frac{N+1}{N-1}} \alpha_{U(1),crit}^{-1}. \quad (86)$$

The most significant conclusion for MPM, predicting from the Multiple Point Principle (MPP) the values of gauge couplings being so as to arrange just the (multiple critical) point where most phases meet, is possibly that our calculations suggest the validity of an approximate universality of the critical couplings, in spite of the fact that we are concerned with first order phase transitions. We have shown (by approximate success) that one can crudely calculate the phase transition couplings without using any specific lattice, rather only approximating the lattice artifact monopoles as fundamental (pointlike) particles condensing. The details of the lattice — hypercubic or random, with multiplaquette terms or without them, etc. — do not matter for the value of the phase transition coupling so much. Such an approximate universality is, of course, absolutely needed if there is any sense in relating lattice phase transition couplings to the experimental couplings found in nature. Otherwise, such a comparison would only make sense if we could guess the true lattice in the right model, what sounds too ambitious.

It must be admitted though that we only properly compared the Parisi improved couplings which are not the same ones as the couplings corresponding to the scale of the monopole mass. The corrections used were taken from the $U(1)$ case in which one has both the Parisi improved and the long scale distance phase transition couplings at disposal.

If we could drive the comparison of the phase transition couplings for the different groups to a higher accuracy, we might seek in MPM to make the comparison of different critical couplings somewhat similar to the studies in the GUT models.

ACKNOWLEDGMENTS: We are greatly thankful to Y.Takanishi for useful discussions and help.

One of the authors (L.V.L.) is indebted to the Niels Bohr Institute for its hospitality

and financial support.

Financial support from grants SCI-0430-C (TSTS) and CHRX-CT-94-0621 is gratefully acknowledged by H.B.Nielsen.

We want to thank N.Mankoc-Borštnik and the Slovenian Ministry of Science and late Professor Plemejl for the meetings we had in the House of Plemejl in Bled.

Also H.B.N. thanks the Bergsoe Foundation for the prize for popularization.

Fig. 1

The effective potential V_{eff} : the curve 1 corresponds to the "Coulomb"-
 "confinement" phase transition; curve 2 describes the existence of two
 minima corresponding to the confinement phases.

Fig. 2: The one-loop (curve 1) and two-loop (curve 2) approximation phase diagram in the dual Abelian Higgs model.

Fig. 3
